KEYWORDS
Road traffic, ant algorithm, multiagent systems, neural networks

ABSTRACT
Decision support system for road traffic management can be used for freight transport, people transport but also for site evacuation. We deal with two aspects of the decision support system in a same global architecture: one for traffic regulation to avoid jam and the other for road users to choose the shortest path in time between two points. These two aspects interact. The cartography is represented by a weighted digraph. The weights evolve according to the traffic and the graph is therefore dynamic. The regulation system is based on a neural network. The shortest path is based on an ant algorithm well suited for dynamic environments.

GLOBAL ARCHITECTURE FOR ROAD TRAFFIC MANAGEMENT
The transport development must face up to many constraints like: substructures realization and expansion limitation due to the available space and the costs, reduction of the loud and atmospheric pollution, deregulation and concurrency between the mode of transport and so on. So, it is necessary to find solutions to manage road traffic. Two aspects can be considered. The first one is about Decision Support System (DSS) to help and inform users. The second one is about regulation system based on control amenagement (Virtual Message Signs (VMS), traffic lights, ...).

We propose a global architecture based on two main parts (see figure 1):

- The real world which is split in three elements:
  - the traffic which contains, in one hand, all mobile elements (cars, pedestrians, ...) described with different levels of autonomous behaviour and, in the other hand, spatio-temporal organizations which are predictable (school outs, ...) or not (jam, accident, ...);
  - the environment which contains all the road infrastructure and logistic planning;
  - the control system which contains sensors (webcams, data traffic magnetic sensors, ...) and effectors (VMS, traffic lights, ...).

- The model which is split in the following elements:
  - information collection and processing in order to use them on the solving level;
  - a dynamic weighted digraph representing these informations and the traffic flow;
  - a regulation system based on this graph and managing the control system;
  - a DSS which use the dynamic graph and the regulation control. A multimodal interface informs and helps different users with respect to their profiles.

The information update and its adaptive treatment give the dynamic aspect of the global architecture as described in figure 1. So, it is typically a complex system model including retro-action phenomena. In this paper we develop two points of this architecture: the regulation system based on multi-layer perceptron with backpropagation algorithm and the decision support system which suggests shortest paths obtained from a dynamic graph.

REGULATION MODELLING
The model for road traffic regulation uses an agent-based representation for road traffic and a neuronal model for the regulation. This study (Foote, 2002) presented in the following will look at traffic flow on a Manhattan-style road grid. At each crossroad, there is a traffic lights system deciding which cars are going to cross. Cars enter the grid from the outside and decide which direction they wish to use at each crossroad. We use the Madkit package (Gutknecht and Ferber, 1997) to manage the agent world. The neural network is a multi-layer perceptron implementing a backpropagation algorithm.
Controlling Multi-Agent System

The generic agent organization used in this work is based on a theoretical study of A. Cardon (Lesage et al., 1999). He describes how a multi-agent system can be divided into three types of agents:

- **Aspectual Agents** are the basic agents that represent the target population. In our case, they represent cars and traffic lights in a town;

- **Morphological Agents** deal with aspectual agents measurements. They collect only some informations which lead to describe evolutive and adaptive organizational aspects. It is a kind of projection of all agent characteristics onto a smaller dimensional space. In our case, a morphological agent plays a statistic collection service, taking into account for example, cars position and information about their displacements.

- **Analytical Agents** are some rulers of our agent population, looking at the statistics provided by the morphology agents, and then acting on them to control the global behaviour of the system. The analytical agents do not directly modify the behaviour of any particular agent, but rather, indirectly shape the evolution of the aspectual agents as a whole.

Here, we present an application of this theoretical model, based on a neural network. Our problem is as follows: how can we maximise the flow of traffic through a road network? The input layer of our neural network will process information from the morphological space of the aspectual agents and then give an output figure which represents the global state of the network. This figure can then be used to decide on the action to be taken to increase traffic flow.

**Neuronal Approaches Based Models**

The regulation model uses an agent-based description which is analysed by a neural network based on multi-layer perceptron.

**Agent-Based Description**

The simulator is decomposed in three main parts:

- The *environment* is a bidimensional grid composed of set of roads which have their own length and width and where cars evolve;

- The *traffic lights* manage the cars circulation at each crossroad. Each one finds out the identities of its neighbours, it looks for cars which arrive at its crossroad and knows the direction that each car wants to go. A cooperative light mode is defined and proceed sorting car queues. The longest queue is first managed and the associated light lets cars go to their chosen direction if space is available, else the second-longest queue acts and so on ...

- The *cars* can be in one the three following states. They are in the state *moving* when they have to go to one crossroad (graph node) to another if there is no car in front of it. When a car reaches its chosen crossroad
without having other cars in front of it, it changes its state to atLight one. In this state, it sends a message to the light telling which way it wants to go. It then waits until the light gives it permission to move. If a car has other ones in front of it, during its move, it changes its state to the waiting one.

Moreover, the simulation manages input and output fluxes between the simulated town (as Manhattan-style road grid) and the exterior.

**Multi-Layer Perceptron Regulation**

The neural network used for the regulation is a multi-layer perceptron. It is the analysis layer of the generic agent organisation described previously (see figure 2).

The network computes global variables to reduce traffic jams. The three states of its output are: clear, busy and getting blocked corresponding to no danger of gridlock, slight danger and danger of gridlock. So the retro-action of this analysis layer on the aspectual layer consists in altering the following variables:

- **waitTime** corresponds to the delay between sending batches of cars through the lights;
- **carDispersion** corresponds to the authorized cars number able to come into the town from the exterior.

**Experimentations**

We show in figure 3, two windows of the visual interface desktop of the simulator which represent respectively a schematic view of the traffic and a traffic observer curve. This last information gives the number of cars which are moving at each step of the simulation. In this example, the regulation leads to the preservation of the fluidity, the global number of moving cars is preserved between 100 and 150 units.

**CONSTRAINED PATHS COMPUTATION BASED ON ANT ALGORITHM**

Ant algorithms are a class of meta-heuristics that can yield near-optimal solutions to hard optimization problems. They maintain a population of agents that exhibit a cooperative behaviour (Langton, 1987). For example, ants deposit *pheromones* in the environment that influence others which tend to follow it. Such an approach is robust and well supports parameter changes in the problem. Ant algorithms have been applied successfully to various combinatorial optimization problems like the Traveling Salesman Problem (Dorigo and Gambardella, 1997), routing in networks (Caro and Dorigo, 1997), (White, 1997), for distributed simulation (Bertelle et al., 2002b) but also to DNA sequencing (Bertelle et al., 2002a), graph partitioning (Kuntz et al., 1997) and clustering (Faieta and Lumer, 1994).

**Dynamic Graph and Regulation Feed-back**

The cartography is represented by a weighted digraph $G = (\mathcal{V}, \mathcal{E})$ where $\mathcal{V}$ is a set of vertices representing crossroads or any other significant information (school, town hall . . . ) and $\mathcal{E} = \mathcal{V} \times \mathcal{V}$ is a set of directed edges $e = (v_i, v_j)$. Thus each segment of a street that is between
two adjacent vertices as defined previously is represented by either one or two directed edges. Two directed edges, one in either direction, are used if the street is two-way, and a single directed edge is used if it is a one-way segment. The edge weight \( w_{ij} \) between the vertices \( v_i \) and \( v_j \) is a dynamic factor which represents the time to cross the edge \((v_i, v_j)\) and the traffic load which is compute by the regulation system, as described in the following.

The regulation system which acts on \( \text{waitTime} \) variable, is able to give \( N_{ij} \) the cars number on each edge of the graph modelling the road traffic. Taking into account some physical characteristics of each road modeled with edge, a characteristic fluidity-based time, expressed as:

\[
\delta_{ij} = \left( \frac{F_{ij}}{N_{ij}} \right)^{-1}
\]

This characteristic time contributes to the regulation feedback of the regulation system on the dynamic graph modelling the road traffic. In fact, each edge weight is the sum of an observed time for crossing the road, noted \( r_{ij} \) and the characteristic fluidity-based time defined above:

\[
w_{ij} = r_{ij} + \delta_{ij}
\]

Weights evolve according to the traffic and the graph is therefore dynamic and we have to find paths in this graph. These changes are one of the major motivation for using ant algorithms Ant algorithms which are well suited for that kind of dynamic task. This approach is implicitly distributed. This would not create many communications since the algorithm only uses local informations and stores results directly in the graph (that is, directly in the computing resources local memory).

**Algorithm**

We search in the graph some paths between two vertices \( v_0 \) and \( v_n \). The resolution method is distributed and based on auto-organization mechanisms. We continually release numerical ants on the dynamic graph, and allow them to find routes between pairs of vertices. The ants deposit numerical pheromones on edges. The amounts of pheromone deposited is a function of the length and congestion of paths. Ants are attracted by weights of edges and pheromones. The evaporation allows to forget bad paths. The ants tend to converge on paths which are the fastest. To be able to distribute the computation, we have divided the algorithm in two parts and for each we have a specific time.

- **The environment.** It is represented by the dynamic graph. Its major role is to manage the ant population, evaporation phenomenon and simulation of weights on the edges. We store also in the vertex \( v_n \) the shortest path which comes from \( v_0 \), the minimal global cost \( W_{on} \) of the path from \( v_0 \) to \( v_n \). Due to the dynamic change of weights the duration of the shortest path may change when another ant covers the path crossing the same vertices and we note \( t_{on} \) the instant where the ant has found the same path. For a given step, we have:

\[
t_{on} = \text{discrete time of the environment}
\]

**BEGIN**

- birth of ants on the vertex \( v_0 \)
- pheromone evaporation (see (2))
- weights update
  - IF \( t_{on} < t_{env} \) THEN \( W_{on} = +\infty \) ENDIF
  - // No ants on the path since a long time
  - \( t_{env} = t_{env} + 1 \)
**END**

- The ants. Ants try to go from the vertex \( v_0 \) to the another vertex \( v_n \). Ants manage their displacements according to times and pheromones. They also drop pheromones on edges. Three states are possible for an ant looking for food, reaching the final vertex \( v_n \), and coming back to the source. For one ant located on \( i \) we have:

\[
t_{ant} = \text{discrete time for the ant vertex} = i
\]

**BEGIN**

- ant_state \( \in \{ \text{search, arrived, go_back} \} \)
- vertex = \( i \)
- \( \text{FORALL} \ j \in V_i \) DO
  - Compute the probability \( p_{ij} \) (see (1)) that the ant chooses to hop from the vertex \( i \) to \( j \)
- \( \text{ENDFOR} \)
  - Select the next vertex \( v_k \) according to the probability \( p_{ij} \)
- Wait during the time \( \Delta t_k = 1 \)
- IF \( v_k = v_n \) // Move to \( k \)
  - IF \( t_{ant} = t_{on} \)
    - THEN ant_state = arrived
    - **ENDIF**
  - **ENDIF**
- ant_state = go_back
**BEGIN**

- Update if necessary shortest path and times \( t_{on} \)
- ant_state = go_back
**END**
- ant_state = arrived
**BEGIN**

- pheromone deposit on path used by the ant (see (4))
- death of the ant
**END**

\( t_{ant} = t_{ant} + 1 \)
**END**

Let \( r_{ij} \) be the amount of pheromone trail deposited on the edge connecting \( i \) and \( j \). \( w_{ij} \) the weight of the edges which
depends on the time of the traffic flow to connect the location i and j, it is a dynamic variable. The probability that an ant when it is located on i choose j is:

\[ p(i, j) = \frac{(\tau_{ij})^\alpha \times (\frac{1}{\delta_{ij}})^\beta}{\sum_{k \in \mathcal{V}_i} (\tau_{ik})^\alpha \times (\frac{1}{\delta_{ik}})^\beta} \]  

Where \( \mathcal{V}_i \) is the set of adjacent vertices of i which have not been traversed yet by the ant. The amount of pheromone \( \tau_{ij} \) on the edge \((i, j)\) is modified by the environment and by the ants. The environment regularly updates this pheromone quantity using an evaporation rate, noted \((1 - \rho)\):

\[ \tau_{ij} = \rho \tau_{ij}^{old} \]  

where \( 0 \leq \rho \leq 1 \) and \( \tau_{ij}^{old} \) and \( \tau_{ij}^{new} \) are respectively the pheromone quantity before and after the update. An ant which has found a path between the two vertices \( v_0 \) and \( v_n \) and so come back to start vertex, modify the pheromone quantity by reinforcement rate, noted \( \Delta \tau \):

\[ \Delta \tau = \frac{K}{W_{ij}} \]  

where \( K \) is a constant and \( W_{ij} \) the global cost of the path between i and j.

\[ \tau_{ij}^{new} = \tau_{ij}^{old} + \Delta \tau \]

**Results**

We show an example of the algorithm execution, based on a simple urban representation with a ring road (see figure 4). The first graph shows the initial situation, the ring road is the fastest way then we jam it, so a new path is detected by the ants. The second graph shows the shortest path obtained which takes the ring road, the last one is the solution when the ring road is jammed. In this example, at each environment time step 10 ants are released, \( \alpha = 3, \beta = 1, \rho = 0.9 \) and \( K = 2 \).

**CONCLUSION**

We are developing an architecture of both a regulation system and a decision support system based on a dynamic graph. Ant algorithms are used and well suited for adaptive aspects and anytime approaches of dynamic traffic flow. Neural networks are used and well suited for traffic flow regulation. We actually work on future development concerning management of heterogeneous informations flows from any kind of sources (satellites, webcams, sensors) and multimodal interfaces for the different users. We are searching to extract the most important and urgent informations using organizations of cooperatives/antagonists agents. Multi-agent systems are adapted to find emergent evolutionary solutions in dynamic problems.
